14 Abstract

Prediction of extreme events under climate change is challenging but essential for risk 15 management of natural disasters. Although earth system models (ESMs) are arguably 16 our best tool to predict climate extremes, their high computational cost restricts the ap-17 plication to project only a few future scenarios. Emulators, or reduced-complexity mod-18 els, serve as a complement to ESMs that achieve a fast prediction of the local response 19 to various climate change scenarios. Here we propose a data-driven framework to em-20 ulate the full statistics of spatially resolved climate extremes. The variable of interest 21 is the near-surface daily maximum temperature. The spatial patterns of temperature vari-22 ations are assumed to be independent of time and extracted using Empirical Orthogo-23 nal Functions (EOFs). The time dependence is encoded through the coefficients of lead-24 ing EOFs which are decomposed into long-term seasonal variations and daily fluctua-25 tions. The former are assumed to be functions of the global mean temperature, while 26 the latter are modelled as Gaussian stochastic processes with temporal correlation con-27 ditioned on the season. The emulator is trained and tested using the simulation data in 28 CMIP6. By generating multiple realizations, the emulator shows significant performance 29 in predicting the temporal evolution of the probability distribution of local daily max-30 imum temperature. Furthermore, the uncertainty of the emulated statistics is quanti-31 fied to account for the internal variability. The emulation accuracy in testing scenarios 32 remains consistent with the training datasets. The performance of the emulator suggests 33 that the proposed framework can be generalized to other climate extremes and more com-34 plicated scenarios of climate change. 35

³⁶ Plain Language Summary

Extreme events in the global climate system, such as heat waves and hurricanes, 37 cause incalculable losses every year. Conventional climate models, called Earth System 38 Models (ESMs), are our best tools to predict how climate change may affect the occur-39 rence rate of extreme events in the future. However, these models are relatively slow and 40 expensive to run. We present a framework to design emulators, or reduced-complexity 41 models, to efficiently predict the complete statistics of climate extremes on spatially-resolved 42 grids. Once trained using a few simulations generated from ESMs, the emulator can be 43 used to predict climate change scenarios that were not included in the training data. Our 44 approach is demonstrated for near-surface daily maximum temperature data. The mean, 45 variance, and extreme values of the temperature generated by the emulator are very sim-46 ilar to the statistics generated by ESMs. Furthermore, the emulator provides a speedy 47 quantification of the uncertainty of the predicted statistics. The performance of the em-48 ulator suggests that our framework can be generalized to other types of extreme events 49 in the climate system. 50

51 **1** Introduction

Unprecedented climate extremes, associated with anthropogenic global warming, 52 have been observed worldwide, such as the Russian heatwaves in 2010 and the record-53 breaking Atlantic hurricane season in 2020 (Meehl & Tebaldi, 2004; Barriopedro et al., 54 2011; Reed et al., 2022). The annual losses from such weather- and climate-related dis-55 asters have surged dramatically, escalating from several billion dollars in 1980 to 200 bil-56 lion in 2020 (Allen et al., 2012; AON, 2020), not to mention the incalculable loss of lives. 57 Effectively managing the risks of extreme events and minimizing their associated dam-58 ages necessitates accurate quantification of their likelihood in a rapidly changing global 59 climate. Despite the increased frequency of extreme weather events, their probability at 60 a given time and location is still very low, and thus quantifying their risks requires large 61 ensembles of numerical simulations for very long time horizons. The need for ensembles 62 of simulations amplifies the already high computational cost associated with running full-63

scale Earth System Models (ESMs) and restricts their application to a limited number
 of climate change scenarios. In contrast, emulators, or reduced-complexity models, pro vide a more efficient evaluation of the statistics of extreme events in response to more
 diverse scenarios. In the present work, we develop a multivariate Gaussian stochastic emulator that estimates the probability distribution of local daily maximum temperature
 on spatially-resolved grids.

Climate emulators can be broadly categorized by the spatial resolution of their pro-70 jections. The first type of emulators, also known as simple climate models (SCMs), fo-71 72 cus on modelling how global or regional mean fields are influenced by the concentrations of greenhouse gases, emissions of aerosols, and natural effective radiative forcing vari-73 ations (Meinshausen et al., 2011; Seneviratne et al., 2016). A majority of these emula-74 tors have been systematically compared in the Reduced Complexity Model Intercompar-75 ison Project (Z. R. Nicholls et al., 2020; Z. Nicholls et al., 2021), by evaluating their pre-76 diction accuracy of the global mean temperature. Based on this type of emulators, in-77 teractive models have been developed for policymakers and stakeholders to actively ex-78 amine the impact of energy, economic and public policies on climate change (Kapmeier 79 et al., 2021; Rooney-Varga et al., 2021). 80

The second type of emulators specialize in predicting the response of local variables 81 to climate change. The most widely used method for this type of emulator is pattern scal-82 ing, where the climate variables at different locations are assumed as independent lin-83 ear functions of the global mean temperature (Mitchell, 2003). Therefore, the global mean temperature predicted by the first-type emulators can be used as an input for pattern 85 scaling, facilitating localized climate predictions in response to a variety of emission sce-86 narios. Over time, the framework of pattern scaling has evolved to encompass a broader 87 range of techniques. These advances include the adoption of response functions to ac-88 count for past trajectories of CO₂ (Castruccio et al., 2014; Freese et al., 2024), the use 89 of Matern covariance functions for modeling spatial correlation (Alexeeff et al., 2018), 90 and the incorporation of internal variability through autoregressive processes or the spec-91 trum of principal components analysis (Beusch et al., 2020; Link et al., 2019). As mod-92 ern machine learning methods emerge, researchers have explored diverse architectures 93 to enhance the accuracy of local climate emulation, utilizing inputs ranging from globally-94 averaged emissions to spatial distribution of aerosols. Most of these machine learning 95 models have been evaluated on the benchmark datasets, with ClimateBench (Watson-96 Parris et al., 2022) and ClimateSet (Kaltenborn et al., 2023) being the most commonly 97 used ones. Compared with pattern scaling, neural networks can provide a more accu-98 rate emulation of certain variables, such as the global precipitation, when trained on suf-99 ficiently large ensembles of simulations (Lütjens et al., 2024) albeit with a compromise 100 in the model complexity. 101

Both classes of emulators have been typically used to predict time-averaged quan-102 tities. Only a few recent studies have explored emulating the statistics of climate extremes, 103 such as the annual maximum temperature and the duration of hot waves within a year 104 (Tebaldi et al., 2020; Quilcaille et al., 2022). Furthermore, no prior work has been re-105 ported on the emulation of probability distribution of local climate variables, which con-106 stitutes the primary objective of our research. We introduce a stochastic model to em-107 ulate the statistics of climate extremes, utilizing temperature-related extreme events as 108 a prototypical application. We first extract the empirical orthogonal functions (EOF) 109 (Lorenz, 1956; Hannachi et al., 2007) of the spatial patterns of near-surface daily max-110 imum temperature (TMX) fields to reduce the dimensionality of the system while main-111 taining a high spatial resolution. Driven by the observed nearly-Gaussian character of 112 the EOF statistics (conditioned over season and year), we model the temporal evolution 113 of the EOF coefficients as Gaussian stochastic processes (Mohamad & Sapsis, 2015; Arbabi 114 & Sapsis, 2022), characterized by long-term trends, seasonal variations, and colored noise. 115 The mean, variance and covariance of the EOF coefficients are parameterized using the 116

Figure 1. (a,b) The first and second spatial EOFs of daily maximum temperature, computed using CNRM-CM6-1-HR simulation data. (c) Cumulative variance ratio represented by leading EOFs.

global mean temperature and season, thus generalizing our emulator to more diverse climate change scenarios. A similar framework has been applied to emulate monthly-averaged
temperature and humidity (Geogdzhayev et al., 2024). Our work will focus on daily maximum temperature and its full statistics.

The content of this paper is organized as follows. In §2 we introduce the simulation data used for training and testing the emulator. The mathematical framework of the emulator is described in §3, including the dimensionality reduction method in §3.1 and stochastic modeling of time series in §3.2. The emulation results are presented in §4, followed by a summary of the main conclusions and discussion in 5.

126 2 Data

Among all the ESMs in Coupled Model Intercomparison Project Phase 6 (CMIP6), 127 we adopted the CNRM-CM6-1-HR and MPI-ESM1-2-LR model outputs as our reference 128 dataset. Both models achieved reasonable skill scores on simulating the statistics of cli-129 mate extremes according to a recent evaluation of the performance of CMIP6 models (Wehner 130 et al., 2020). The CNRM-CM6-1-HR model provides the highest spatial resolution (nom-131 inal resolution 50km) among CMIP6 models, which best fits our needs to develop a spatially-132 resolved emulator. However, this model only has one realization available, which is in-133 sufficient to assess the influence of climate internal variability on the emulator. The MPI-134 ESM1-2-LR data feature a large ensemble of realizations, although the spatial resolu-135 tion (250km) is problematic for studying climate extremes. Therefore, the majority of 136 our results will focus on emulation of CNRM-CM6-1-HR data, while the large ensem-137 ble data of MPI-ESM1-2-LR will be utilized to investigate the impact of internal vari-138 ability and ensemble size on the performance of the emulator. 139

Two variables are collected from the CNRM-CM6-1-HR and MPI-ESM1-2-LR model 140 outputs: (i) Near-surface daily mean temperature (the tas variable in CMIP6), used to 141 compute the global mean temperature; (ii) Near-surface daily maximum temperature (the 142 tasmax variable in CMIP6). Here "near surface" refers to two-meter height according 143 to the CMIP6 convention. The CMIP6 simulations cover a historical period from 1850 144 to 2014, followed by a set of future scenarios until 2100. The CNRM-CM6-1-HR model 145 offers only one realization for both the historical period and each future scenario, whereas 146 the MPI-ESM1-2-LR model provides 50 realizations. To train the emulator, we utilize 147 the simulation data within the historical period and the SSP5-8.5 future scenario for each 148 ESM. The SSP1-2.6 future scenario is utilized for testing purposes. 149

150 3 Methods

151

3.1 Data pre-processing: dimensionality reduction

Since we focus on the near-surface temperature, the spatial location \boldsymbol{x} is described 152 by the latitude and longitude coordinates, $\boldsymbol{x} = (\theta, \varphi)$, where $\theta \in [-\pi/2, \pi/2]$ and $\varphi \in$ 153 $[0, 2\pi)$. The time step size is one day, and the number of days since 01/01/1850 0:00 is 154 represented as t. The daily maximum temperature (TMX) at location x and time t for 155 the ensemble member ω is denoted as $q(\boldsymbol{x}, t, \omega)$. The climatological mean $\bar{q}(\boldsymbol{x}, t)$ is ex-156 tracted by phase-averaging TMX for the same calendar day and location across the his-157 torical period, 1850-2014, and over the entire ensemble. In other words, at an arbitrary 158 time $t, \bar{q}(\boldsymbol{x}, t) = \bar{q}(\boldsymbol{x}, \text{mod}(t, 365))$. The fluctuations of TMX are decomposed as super-159 position of Empirical Orthogonal Functions (EOFs), $\phi_i(\boldsymbol{x})$, 160

$$q'(\boldsymbol{x},t,\omega) \coloneqq q(\boldsymbol{x},t,\omega) - \bar{q}(\boldsymbol{x},t) = \sum_{i} a_{i}(t,\omega)\phi_{i}(\boldsymbol{x}).$$
(1)

In order to compute the EOFs, we construct the spatial covariance function $\mathcal{R}(\boldsymbol{x}, \boldsymbol{x}^*)$ that quantifies the covariance between fluctuating TMX at two arbitrary locations \boldsymbol{x} and \boldsymbol{x}^* ,

$$\mathcal{R}(\boldsymbol{x}, \boldsymbol{x}^*) = \langle q'(\boldsymbol{x}, t, \omega) q'(\boldsymbol{x}^*, t, \omega) \rangle_{t\omega} \,. \tag{2}$$

The notation $\langle \cdot \rangle_{t\omega}$ represents averaging over time and the ensemble. The EOFs are de-

fined as the eigenfunctions of $\mathcal{R}(\boldsymbol{x}, \boldsymbol{x}^*)$, taking into account the curvature of the Earth's surface S,

$$\int_{S} \mathcal{R}(\boldsymbol{x}, \boldsymbol{x}^{*}) \phi_{i}(\boldsymbol{x}^{*}) \cos \theta^{*} d\theta^{*} d\varphi^{*} = \lambda_{i} \phi_{i}(\boldsymbol{x}).$$
(3)

The coefficient of each EOF at time t is obtained by projecting $q'(x, t, \omega)$ onto $\phi_i(x)$,

$$a_i(t,\omega) = \int_S q'(\boldsymbol{x}, t, \omega)\phi_i(\boldsymbol{x})\cos\theta d\theta d\varphi.$$
 (4)

Similar to the climatological mean, the EOFs are also computed from the historical data.
However, we only utilize the TMX snapshots on every five days, rather than daily data,
because TMX on adjacent days are highly correlated. Our choice of five-day interval is
based on the observation that on this timescale the autocorrelation coefficient of TMX
at most locations decreases to approximately 0.5 (Kalvová & Nemesšová, 1998), striking a reasonable balance between data independence and comprehensive representation
of temperature variability.

For CNRM-CM6-1-HR data, since only one realization is available, the number of 175 snapshots (1.2×10^4) is much smaller than the number of grids (2.6×10^5) . As such, it 176 is unnecessary to store the large covariance matrix (2), and the method of snapshots is 177 adopted to solve the eigenvalue problem (3) more efficiently. Specifically, we compute 178 the temporal covariance matrix of q', whose size is the square of the number of snapshots. 179 The eigen-decomposition of the temporal covariance matrix is then performed to get its 180 eigenvalues and eigenfunctions, which can be linearly transformed to get the eigenpairs 181 $(\lambda_i, \phi_i(\boldsymbol{x}))$ of the spatial covariance $\mathcal{R}(\boldsymbol{x}, \boldsymbol{x}^*)$. More details can be found in Sirovich (1987) 182 and Taira et al. (2020). For MPI-ESM1-2-LR data, the number of grids (1.8×10^4) is 183 comparable or smaller than the total number of snapshots $(1.2 \times 10^4 \times \text{the number of})$ 184 realizations adopted), and we directly solve equation (3) to obtain the eigenfunctions of 185 the spatial covariance. 186

The first two EOFs of the CNRM-CM6-1-HR data are visualized in figure 1(a,b). They account for 2.9% and 2.7% of the total variance, respectively. Both EOFs are reminiscent of the Arctic Oscillation/Northern Hemisphere Annular Mode (Thompson & Wallace, 1998) and the Southern Hemisphere Annular Mode (Fogt & Marshall, 2020). Unlike previous studies that focused on the first few EOFs to extract the physically significant modes (Wallace & Gutzler, 1981; Amaya, 2019), our objective is to reconstruct the

Figure 2. Jun-Aug mean of (*a*) the first and (*b*) second EOF coefficients in each year of CNRM-CM6-1-HR dataset, from 1850 to 2100, plotted versus the global mean temperature. Red dots: true seasonal mean obtained from the historical and SSP5-8.5 scenario. Green dots: SSP1-2.6 scenario. Black dashed line: linear regression; Solid line: machine-learned function.

full probability distribution of local TMX with sufficient accuracy and efficiency. Therefore, we retain the first 2,000 EOFs for the CNRM-CM6-1-HR model, which altogether represent approximately 95% of the total variance (figure 1c) of the respective datasets.

3.2 Multivariate Gaussian stochastic emulator of EOF time series

196

Assuming the climatological mean and EOFs remain invariant with respect to time
 and future scenarios, our stochastic emulator of the daily maximum temperature is for mulated as,

$$\hat{q}(\boldsymbol{x},t,\hat{\omega}) = \bar{q}(\boldsymbol{x},t) + \sum_{i=1}^{I} \hat{a}_i(t,\hat{\omega})\phi_i(\boldsymbol{x}).$$
(5)

A notable difference between equation (5) and the decomposition of true TMX fluctuations (1) is the EOF coefficient, where *a* is the true coefficient obtained from projection (4) and \hat{a} is estimated from the emulator. The emulation index $\hat{\omega}$ is also different from the ensemble member ω , since the emulator can be used to generate more realizations than the training data.

The time series of \hat{a} in season *s* and for a given global mean temperature, is modelled as superposition of long-term trends and Gaussian-distributed daily fluctuations that encode temporal correlation:

$$\hat{a}_{s,i}(t,\hat{\omega}) = \hat{\mu}_{s,i}(T_{s,g}) + \hat{\sigma}_{s,i}(T_{s,g}) \sum_{j=1}^{I} \hat{l}_{s,ij} \hat{\eta}_{s,j}(t,\hat{\omega}), \quad i = 1, 2, \dots, I.$$
(6)

The subscript s = 1, 2, 3, 4 corresponds to Northern Hemisphere spring (Mar-May), sum-208 mer (Jun-Aug), autumn (Sep-Nov), and winter (Dec-Feb) respectively. The seasonal mean 209 $\hat{\mu}_{s,i}$ and variance $\hat{\sigma}_{s,i}^2$ are parameterized as a function of the seasonally-averaged global 210 mean temperature, $T_{s,q}$. The correlation between the *i*th and *j*th EOFs in season s is 211 assumed constant and accounted for by $\hat{l}_{s,ij}$. The daily fluctuations of the EOF coeffi-212 cients are modelled as superposition of Gaussian autoregressive processes $\hat{\eta}_{s,i}(t,\hat{\omega})$. Here 213 $\hat{\eta}_{s,j}$ and $\hat{\eta}_{s,k}$ are uncorrelated when $j \neq k$, and the time series of $\hat{\eta}_{s,j}$ are emulated usi-214 ing the autocorrelation computed from training data. Specifically, consider a time win-215 dow in season s of the y-th year, denoted as $t \in [t_{ys}, t_{ys} + N_s]$. The starting time, t_{ys} , 216 corresponds to the first day of each season: Mar 1st, Jun 1st, Sep 1st, and Dec 1st, for 217 $s = \{1, 2, 3, 4\}$. The duration of each time window, N_s , is given by $N_s = \{92, 92, 91, 90\}$ 218 days respectively. Within $t \in [t_{ys}, t_{ys} + N_s]$, the emulated daily fluctuations $\hat{\eta}_{s,j}(t, \hat{\omega})$ 219 satisfy 220

$$\hat{\eta}_{s,j}(t,\hat{\omega}) = \sum_{n=1}^{t-t_{ys}} c_{s,j}(n)\hat{\eta}_{s,j}(t-n,\hat{\omega}) + g_{s,j}(n)\epsilon_{s,j}(n), \quad \epsilon_{s,j}(n) \sim \mathcal{N}(0,1), \quad t \in [t_{ys}, t_{ys} + N_s].$$
(7)

Figure 3. Probability density function (PDF) of the 1st, 2nd, and 500th component of the Jun-Aug η_s : (a) $\eta_{2,1}$, (b) $\eta_{2,2}$, (c) $\eta_{2,500}$. Red dashed lines: PDF computed using CNRM-CM6-1-HR historical and SSP5-8.5 future scenario data, from 1850 to 2100; gray lines: Gaussian fit of $\eta_{2,i}$ data; blue lines: PDF of 10 emulations of 1850-2100 $\hat{\eta}_{2,i}$

The parameters $c_{s,j}(n)$ and $g_{s,j}(n)$ are independent of the year and will be estimated from the training data, while the standard normal random number $\epsilon_{s,j}(n)$ varies with the year and the emulation. The emulator (6) can also be written more compactly in vector form,

$$\hat{\mathbf{a}}_{s}(t,\hat{\omega}) = \hat{\boldsymbol{\mu}}_{s}\left(T_{s,g}\right) + \hat{\mathbf{D}}_{s}\left(T_{s,g}\right)\hat{\mathbf{L}}_{s}\hat{\boldsymbol{\eta}}_{s}(t,\hat{\omega}),\tag{8}$$

where $\hat{\mathbf{a}}_s$, $\hat{\boldsymbol{\mu}}_s$, and $\hat{\boldsymbol{\eta}}_s$ are $I \times 1$ column vectors. The notation $\hat{\mathbf{D}}_s$ is a diagonal matrix, and each element on the diagonal is $\hat{\sigma}_{s,i}$. The matrix $\hat{\mathbf{L}}_s$ is lower triangular, where each entry corresponds to $\hat{l}_{s,ij}$.

It is important to emphasize here that the formulated emulator is conditionally Gaus-228 sian, i.e. for a fixed season and global mean temperature, the daily fluctuations are, by 229 design, normally distributed. While this does not necessarily imply that long term statis-230 tics will have a Gaussian character, since we also have the variation of the global mean 231 temperature, it does not allow for the possibility of daily temperature extremes that have 232 (for a given season and global mean temperature) a non-Gaussian distribution, e.g. fol-233 low heavy tails. For the present context, direct comparisons suggest that this is a accept-234 able assumption. However, for other variables this aspect may introduce limitations. We 235 plan to extend the framework to address these potential limitations in future work. 236

The unknown parameters (which are functions of $T_{s,g}$) in the emulator (6,7) are 237 estimated using the true EOF coefficients $a_i(t,\omega)$ (4) and the global mean temperature 238 $T_{s,q}$ from 1850 to 2100 (historical and SSP5-8.5 scenario). Given $a_i(t,\omega)$ data, we first 239 compute the actual seasonal mean $\mu_{s,i}$ and standard deviation $\sigma_{s,i}$ in each year, aver-240 aged over the entire ensemble. Two examples of the Jun-Aug mean $\mu_{s,i}$ versus the cor-241 responding $T_{s,q}$ are shown in figure 2 (red dots). These relationships are mostly linear 242 and independent of the future scenario (SSP1-2.6 shown in green dots), which motivate 243 us to regress $\hat{\mu}_{s,i}$ as a linear function of $T_{s,g}$ (black dashed lines). Similar linear relationships are also observed for the variance $\sigma_{s,i}^2$ and also for higher-ranked EOFs. Nonlin-244 245 ear functions are also attempted using fully-connected neural networks. For each $\hat{\mu}_{s,i}$ or 246 $\hat{\sigma}_{s,i}^2$, the neural network is designed with two hidden layers, each containing three neu-247 rons, utilizing the ReLU activation function. The learned nonlinear functions are shown 248 as black solid lines in figure 2, which provide slightly better agreement with the train-249 ing data. A more systematic comparison of the emulation results using linear and non-250 linear functions will be provided in §4.1. We also explored alternative network architec-251 tures with varying numbers of layers and neurons, as well as different activation func-252 tions, including Sigmoid and Tanh. However, these modifications did not yield signif-253 icant improvements and the associated results are not shown. 254

Figure 4. Spectra of the 1st, 2nd, and 500th component of the Jun-Aug η_s : (a) $\eta_{2,1}$, (b) $\eta_{2,2}$, (c) $\eta_{2,500}$. Gray circles: spectra averaged using CNRM-CM6-1-HR historical (1850-2014) data; red lines: CNRM-CM6-1-HR SSP5-8.5 (2015-2100) data; blue lines: 10 emulations of 2015-2100 spectra.

After extracting the variation of the seasonal mean and standard deviation in response to the global mean temperature, $\hat{\mu}_{s,i}(T_{s,g})$ or $\hat{\sigma}_{s,i}^2(T_{s,g})$, we remove these trends from the true EOF coefficients, resulting in the residuals $(a_{s,i} - \hat{\mu}_{s,i})/\hat{\sigma}_{s,i}$. We then evaluate their cross-correlations,

$$\hat{\boldsymbol{\Sigma}}_{s} = \left\langle \hat{\mathbf{D}}_{s}^{-1} \left(\mathbf{a}_{s} - \hat{\boldsymbol{\mu}}_{s} \right) \left(\mathbf{a}_{s} - \hat{\boldsymbol{\mu}}_{s} \right)^{\top} \hat{\mathbf{D}}_{s}^{-\top} \right\rangle_{t\omega}, \quad \hat{\boldsymbol{\Sigma}}_{s} = \hat{\mathbf{L}}_{s} \hat{\mathbf{L}}_{s}^{\top}, \tag{9}$$

The time average is performed from 1850 to 2100 for each season respectively. While the actual cross correlations fluctuate over time, they remain statistically stationary for most EOFs, justifying the choice of a constant matrix model. Generalization of (9) to timedependent correlations requires large-ensemble data and will be discussed in §4.2. The last equality in (9) is a Cholesky decomposition of $\hat{\Sigma}_s$. Multiplying the residuals by $\hat{\mathbf{L}}_s^{-1}$ produces uncorrelated time series,

$$\boldsymbol{\eta}_{s}(t,\omega) = \hat{\mathbf{L}}_{s}^{-1} \hat{\mathbf{D}}_{s}^{-1} \left(\mathbf{a}_{s}(t,\omega) - \hat{\boldsymbol{\mu}}_{s} \right), \tag{10}$$

²⁶⁵ which satisfies

$$\left\langle \boldsymbol{\eta}_{s}(t,\omega)\boldsymbol{\eta}_{s}(t,\omega)^{\top}\right\rangle_{t\omega} = \mathbf{I}.$$
 (11)

Here I is an identity matrix with a size equal to the number of adopted EOFs. In other words, each entry of $\eta_s(t,\omega)$ has unit variance, and different entries are uncorrelated.

To justify our assumption that $\eta_{s,j}(t,\omega)$ in season s can be modelled as Gaussian 268 processes (equation 7) with the same autocorrelations across different years, we evalu-269 ate the statistics $\eta_{s,j}(t,\omega)$ in figure 3,4. The probability density functions of the 1st, 2nd, 270 and 500th component of Jun-Aug $\eta_{s,j}$ are computed using historical and SSP5-8.5 sce-271 nario data, from 1850 to 2100. The profiles are plotted by red dashed lines in figure 3, 272 which almost overlap with the fitted Gaussian distributions (gray lines). While not shown 273 here, the other components of $\eta_{s,i}(t,\omega)$ also exhibit approximately Gaussian distribu-274 tions. To examine the time dependence of the second-order statistics of each component 275 of η_s , we compute the Fourier spectra of η_s in Jun-Aug of each year and average them 276 over two distinct time windows, 1850-2014 and 2015-2100 of SSP5-8.5 scenario. As vi-277 sualized in figure 4, the spectra of three components of η_s remain approximately unchanged 278 over time. Therefore, the statistics averaged over the entire 1850-2100 period are used 279 to generate the surrogate Gaussian processes $\hat{\eta}_{s,j}$ that represent stochastic realiza-280 tions of daily fluctuations. Simulation of the Gaussian processes is based on the exact 281 time-domain method which utilizes the autocorrelation of η_s . This approach has been 282 demonstrated more robust against uncertainty of statistics than the frequency-domain 283 method (Percival, 1993). The PDFs of the simulated $\hat{\eta}_s$ in figure 3(blue lines) indeed 284 follow Gaussian distribution, and the Fourier spectra of the simulated processes align 285 with the true spectra, as illustrated in figure 4. 286

Figure 5. (a) Flow chart showing the structure of the emulator. Given the global mean temperature T_g , the emulator predicts the local daily maximum temperature on spatially-resolved grids. (b) One-year moving average of the global mean temperature, shown for different scenarios. (c) Example time series of the true and emulated EOF coefficients. (d) Sample outputs from the emulator: reconstruction of the TMX field. (e) An example of the probability density function of local TMX, averaged in Jun-Aug over a ten-year window. The vertical lines mark the mean values.

The steps of the emulation are summarized schematically in figure 5a. Starting from 287 the temporal evolution of the global mean temperature (panel b), the seasonal mean and 288 variance of the EOF coefficients are estimated from the learned relationships $\hat{\mu}_{s,i}(T_{s,q})$, 289 $\hat{\sigma}_{s,i}^2(T_{s,g})$. The daily fluctuations are constructed as the stochastic autoregressive pro-290 cesses $\hat{\eta}_{s,j}(t,\omega)$, which are scaled by $\hat{l}_{s,ij}$ and superposed to account for the cross cor-291 relation between different EOFs. Combining the scaled daily fluctuations with long-term 292 trends, we obtain the emulated time series of the EOF coefficients, exhibiting the same 293 first and second order statistics as the true time series (panel c). Given the time series 294 and shape of EOFs, the final output of the emulator is the temporal evolution of grid-295 ded local TMX. A sample snapshot of TMX is visualized in panel d. To acquire converged 296 probability distribution of local TMX, especially for the tails that represent extreme events, 297 the statistics are computed by averaging over a decadal window in time and a $1^{\circ} \times 1^{\circ}$ 298 region in space. Panel e shows a sample comparison between the emulated and true prob-299 ability density function (PDF). The blue region marks the uncertainty of the distribu-300 tion, estimated by performing multiple emulations. We note the non-Gaussian charac-301 ter of the target and approximated PDF, which is the result of considering the statis-302 tics over a time window that the global average temperature changes. 303

4 Emulation results

305

4.1 Emulation of CNRM-CM6-1-HR dataset

The performance of the emulator is firstly evaluated in detail for Jun-Aug, when TMX is the most extreme in Northern Hemisphere. Results in other seasons will be briefly discussed at the end of this section. To differentiate between the emulator that adopts

Figure 6. Mean anomaly of Jun-Aug daily maximum temperature, averaged over (a) 2000-2009, (b) 2090-2099 of the SSP5-8.5 scenario, and (c) 2090-2099 of the SSP1-2.6 scenario. Each subfigure shows the true mean from CNRM-CM6-1-HR ESM, two sample emulations, average of 10 emulations, error of 10 emulations, and the error of 10 ML emulations. Reference: 1850-1900 Jun-Aug mean TMX.

linear and nonlinear model for the long-term trends, the former is referred to as "em-309 ulation" and the latter is denoted as "machine-learning (ML) emulation". Figure 6 shows 310 the mean of local TMX across three decadal periods: 2000-2009 within the historical pe-311 riod, 2090-2099 of the SSP5-8.5 scenario, and 2090-2099 of the SSP1-2.6 scenario. The 312 reference mean, computed from the CNRM-CM6-1-HR data, is compared against two 313 sample emulations, the average of ten emulations, and ML emulations. The emulator ac-314 curately captures the evolution of local TMX under both high and low warming scenar-315 ios. Significant anomalies in regions such as the Arctic, western coast of South Amer-316 ica, North Africa, West Asia and Southern Ocean are well reproduced. Errors are within 317 1° C at most locations, with the highest errors reaching 2° C. Using ML model for the sea-318 sonal mean and variance appreciably improves the emulation accuracy. Despite train-319 ing on historical and SSP5-8.5 data only, the emulator performance on the unseen SSP1-320 2.6 scenario demonstrates its potential for application across various climate change path-321 ways. 322

The errors of the emulated mean in figure 6(a-c) arise from different contributions. 323 In figure 6a, the discrepancy between the emulations and the true mean mainly origi-324 nates from the modeling assumption that the seasonal mean is fully determined by the 325 global mean temperature, $\hat{\mu}_{s,i}(T_{s,g})$. As discussed in §3.2 (c.f. figure 2), a single global 326 mean temperature $T_{s,g}$ can correspond to multiple values of the mean EOF coefficients 327 $\mu_{s,i}$, due to the internal variability of the climate system and the neglected influence of 328 the past global mean temperature or emission history. The internal variability of the CNRM-329 CM6-1-HR simulation is difficult to quantify, since only one realization is available. How-330 ever, the variability captured by the emulator can be readily assessed by performing mul-331 tiple emulations. Comparing the pattern of errors with the two emulations in figure 6a, 332 we observe that most high-error regions also exhibit high variability, such as Europe and 333 the Southern Ocean. In addition, the error magnitude aligns with the variability, indi-334 cating that the error can be further reduced if more realizations of the ESM are avail-335 able for training the emulator and computing the local statistics. In figure 6b, smaller-336 scale fluctuation of the errors become more apparent, which stems from the changing shape 337 of the leading EOFs under different warming conditions. Recall that the EOFs were com-338 puted only using the historical data. The leading historical EOFs adopted in the em-339 ulator may represent a lower variance in the SSP5-8.5 scenario, which results in higher 340 emulation errors contributed by truncating EOFs. This issue can be mitigated by includ-341 ing SSP5-8.5 data into the calculation of EOFs, though similar errors might recur when 342 the emulator is applied to unseen scenarios. The error in SSP1-2.6 scenario (figure 6c) 343 is slightly higher than SSP5-8.5, due to the trained model of long-term trends not be-344 ing optimal for SSP1-2.6. The error of ML emulations are even higher than linear em-345 ulations for SSP1-2.6, such as in South America, which indicates that the superior per-346 formance of ML emulator in SSP5-8.5 is likely due to overfitting. Nevertheless, the sen-347 sitivity of the seasonal mean to warming condition is modest, and the emulation error 348 remains the same order of magnitude across different scenarios. 349

The standard deviation of local TMX is presented in figure 7. In historical peri-350 ods, such as 2000-2009 shown in figure 7a, the standard deviation is reconstructed ac-351 curately for most locations. The error from ten emulations is almost identical to the ML 352 emulations, suggesting a predominantly linear relationship between the variance of most 353 EOF coefficients and the global mean temperature, $\hat{\sigma}_{s,i}(T_{s,g})$. From 2000-2009 to 2090-354 2099 in SSP5-8.5 scenario (panel b), the standard deviation slightly increases in most re-355 gions, such as North America, North Africa and West Asia. In contrast, the standard 356 deviation in Greenland and Southern Ocean shows a significant reduction, likely due to 357 diminished ice coverage (Räisänen, 2002; Gao et al., 2015). These trends are consistent 358 with the observational data (Huntingford et al., 2013) and ESM simulations using other 359 models (Olonscheck & Notz, 2017). The performance of the emulator is the least sat-360 isfactory in regions associated with the most significant trends. For example, the enhanced 361 variance in North Africa is not captured, and the decreasing trend in the Southern Ocean 362

Figure 7. Standard deviation of Jun-Aug daily maximum temperature, averaged over (*a*) 2000-2009, (*b*) 2090-2099 of the SSP5-8.5 scenario, and (*c*) 2090-2099 of the SSP1-2.6 scenario. Each subfigure shows the true mean from CNRM-CM6-1-HR ESM, two sample emulations, average of 10 emulations, error of 10 emulations, and the error of 10 ML emulations.

is only partially reproduced. These limitations can be alleviated by relaxing the assumption of the emulator that cross-EOF correlations $\hat{\mathbf{L}}_s$ are constant, which is explored in §4.2. Nonetheless, the underlying climate dynamics, such as the removal of polar amplification due to the loss of ice coverage, is non-linear and non-local, requiring more judicious treatment in the construction of emulators. In the SSP1-2.6 scenario (figure 7c), changes of standard deviation progress more slowly, and the corresponding emulation errors are less severe than in the SSP5-8.5 scenario.

We visualize in figure 8 the 97.5% quantile as an example of extreme temperature. 370 371 It is important to note that the baseline temperature for anomalies in figure 8 differs from that in figure 6; here, it is based on the 1850-1900 97.5% quantile rather than the 1850-372 1900 average. Within 2000-2009, the emulated quantile (figure 8a) is less accurate than 373 the mean (c.f. figure 6a), which is anticipated due to the compounded error from the em-374 ulated standard deviation affecting the quantile estimation. Moreover, the predicted quan-375 tile exhibits greater uncertainty across different emulations, further contaminating the 376 accuracy of averaged emulations. In SSP5-8.5 2090-2099 (figure 8b), the increase of quan-377 tile is similar to the mean (figure 6b) at most locations. An interesting trend can be ob-378 served in South Asia: the quantile grows more significantly than the mean in India but 379 slightly decreases in Ganges Delta. Since the standard deviation in South Asia remains 380 approximately unaffected by the global warming, the change of extreme temperature pre-381 dominantly indicates heavier or thinner tails of the probability distribution. These trends 382 are successfully identified by the emulator. The highest error of the emulated quantile 383 occurs in Greenland and the Southern Ocean, due to the overestimated standard devi-384 ation as discussed in figure 7. Other error patterns primarily originate from the inter-385 nal variability, as explored by analyzing the temporal evolution of the emulated quan-386 tile from 2010 to SSP5-8.5 2100 (Appendix Appendix A). When applied to the testing 387 data under the SSP1-2.6 scenario (figure 8c), the emulator effectively captures the warm-388 ing patterns of extreme temperatures with accuracy comparable to the training data in 389 figures 8(a,b). Using the ML model for long-term trends does not improve the quantiles 390 of TMX in SSP1-2.6 scenario. 391

The probability density functions of local TMX are plotted in figure 9 at three $1^{\circ} \times$ 392 1° small regions that include major cities: Boston, situated in proximity to the Atlantic 393 Ocean; Tehran, featured by the semi-arid climate with hot dry summers; Shanghai, char-394 acterized by the subtropical maritime monsoon climate. All these locations exhibit a sig-395 nificant increase of the extreme temperature in SSP5-8.5 scenario (c.f. figure 8). Over-396 all the emulated PDFs closely match their true profiles, although the deviations in the 397 SSP5-8.5 scenario are more appreciable. Since the size of samples (3,680) to estimate the 398 true PDF might be insufficient, we quantify the uncertainty by bootstrap resampling, 399 as marked by red shaded regions in figure 9. The uncertainty of emulated PDFs are quan-400 tified using one standard deviation of ten emulations, as shown by blue shaded areas. 401 Taking the uncertainty of PDFs into consideration, the mismatch between emulated and 402 true profiles are less severe. Note that the non-Gaussian shape of the PDF at Tehran 403 (middle row in figure 9) is accurately replicated by the emulator, due to the effect of mix-404 ing instantaneous Gaussian TMX with different mean and variance, as discussed at the 405 end of §3.2. The accurate emulation of the PDFs demonstrate the capacity of the emulator to predict any statistics of theoretical and practical interest, including skewness, 407 kurtosis, and climate extreme indices. 408

The performance of the emulator in different seasons is examined by the root-meansquare error (RMSE) of the statistics and summarized in figure 10. Given a statistic of the reference daily maximum temperature Q and its estimation \hat{Q} , the RMSE is defined as,

$$\text{RMSE} = \left(\frac{1}{S} \int_{S} \left(\hat{\mathcal{Q}} - \mathcal{Q}\right)^{2} \cos\theta d\theta d\varphi\right)^{1/2}.$$
 (12)

Figure 8. Extreme anomaly of Jun-Aug daily maximum temperature, quantified by the 97.5% quantile of local TMX distribution. The quantiles are evaluated using data from (a) 2000-2009, (b) 2090-2099 of the SSP5-8.5 scenario, and (c) 2090-2099 of the SSP1-2.6 scenario. Each sub-figure shows the true mean from CNRM-CM6-1-HR ESM, two sample emulations, average of 10 emulations, error of 10 emulations, and the error of 10 ML emulations. Reference: 1850-1900 Jun-Aug 97.5% quantile of TMX.

Figure 9. Probability density function (PDF) of local daily maximum temperature, averaged over three $1^{\circ} \times 1^{\circ}$ regions that include major cities. Left to right columns: Boston $(42^{\circ}N, -71^{\circ}E)$, Tehran $(36^{\circ}N, 51^{\circ}E)$ and Shanghai $(31^{\circ}N, 122^{\circ}E)$. Red dashed line: CNRM-CM6-1-HR simulation data; red shaded region: uncertainty of the true PDF computed by bootstrapping; solid line: 10 emulations; blue shaded region: uncertainty of PDf quantified by one standard deviation of 10 emulations. The PDF are evaluated in decadal windows: (top row) historical, 2000-2009; (middle row) 2090-2099, SSP5-8.5 scenario; (bottom row) 2090-2099, SSP1-2.6 scenario. TMX are shown using degree Celsius.

The error in mean TMX remains relatively consistent across seasons and future scenar-413 ios. Similarly, the standard deviation error is nearly stationary and independent of sea-414 sons over historical periods. However, in SSP5-8.5 future scenario, seasonal variation be-415 comes more pronounced, with the error in Sep-Nov at the end of the century almost dou-416 bling that of Dec-Feb. The end period of SSP5-8.5 scenario is the most difficult to pre-417 dict, because of the reduced representation accuracy of leading EOFs trained from his-418 torical data. Additionally, the availability of only a single realization limits the emula-419 tor's ability to accurately estimate the most extreme warming conditions. The more pro-420 nounced error in Sep-Nov is due to the more significant influence of global warming on 421 Sep-Nov statistics of TMX. Specifically, the Sep-Nov standard deviation of TMX is de-422 creasing not only in the Southern Ocean, but also in the Arctic, which are not accurately 423 captured by the emulator (see Appendix B for global distribution of standard deviations). 424 The SSP1-2.6 future scenario exhibits similar seasonal error variations, albeit with gen-425 erally lower magnitudes compared to SSP5-8.5. Regarding the 97.5% quantiles, their RMSE 426 patterns align closely with those observed for the standard deviation, reflecting the same 427 underlying climate dynamics. Despite these seasonal variations, the overall error mag-428 nitude remains relatively consistent across all four seasons throughout the emulated time 429 and scenarios, which justifies the application of the emulator across the entire annual cy-430 cle. 431

Figure 10. Root-mean-square error of the mean, standard deviation, and 97.5% quantile of TMX in different seasons. Solid lines: historical and SSP5-8.5 future scenario; dashed lines: SSP1-2.6 future scenario. Blue, green, red, yellow: errors averaged in Dec-Feb, Mar-May, Jun-Aug, Sep-Nov.

4.2 Emulation of MPI-ESM1-2-LR large-ensemble dataset

When a large ensemble of realizations are available, the assumption of constant crossmode covariance in the emulator (equation 9) can be relaxed. Specifically, we generalize the emulator of EOF time series (equation 6) by modeling $\hat{l}_{s,ij}$ as a function of the global mean temperature,

$$\hat{a}_{s,i}(t,\hat{\omega}) = \hat{\mu}_{s,i}(T_{s,g}) + \sum_{j=1}^{I} \hat{l}_{s,ij}(T_{s,g}) \,\hat{\eta}_{s,j}(t,\hat{\omega}), \quad i = 1, 2, \dots, I.$$
(13)

In order to estimate the relation between $\hat{l}_{s,ij}$ and $T_{s,g}$, we follow similar procedures as §3.2. Given the true EOF time series $\mathbf{a}(t)$, we remove the linear trends of seasonal mean $\hat{\mu}_s(T_{s,g})$, compute the covariance of $\mathbf{a}_s - \hat{\mu}_s$ in each year, and perform Cholesky decomposition of the covariance matrix,

$$\bar{\boldsymbol{\Sigma}}_{s}(t) = \left\langle \left(\mathbf{a}_{s} - \hat{\boldsymbol{\mu}}_{s}\right) \left(\mathbf{a}_{s} - \hat{\boldsymbol{\mu}}_{s}\right)^{\top} \right\rangle_{s\omega}, \quad \bar{\boldsymbol{\Sigma}}_{s}(t) = \bar{\mathbf{L}}_{s}(t)\bar{\mathbf{L}}_{s}^{\top}(t), \tag{14}$$

where $\langle \cdot \rangle_{s\omega}$ denotes an average over the ensemble and season s in each year. An intu-

- itive but risky idea is modelling each entry of $\bar{\Sigma}_s(t)$ as a linear function of the global mean temperature. Such a strategy cannot guarantee the positive definite property of the estimated covariance matrix. This limitation can be overcome by modelling $\bar{\mathbf{L}}_s(t)$ as lin-
- timated covariance matrix. This minitation can be overcome by modeling $\mathbf{L}_{s}(t)$ as ear functions of $T_{s,q}$,

$$\hat{\mathbf{L}}_{s}(T_{s,g}) = \hat{\mathbf{P}}_{s,0} + T_{s,g}\hat{\mathbf{P}}_{s,1}.$$
(15)

Since $\hat{\mathbf{L}}_{s}(T_{s,g})$ is lower triangular, $\hat{\mathbf{P}}_{s,0}$ and $\hat{\mathbf{P}}_{s,1}$ inherit this property, and each of their non-zero entries is computed by the method of least squares. Multiplying $\mathbf{a}_{s} - \hat{\boldsymbol{\mu}}_{s}$ by $\hat{\mathbf{L}}_{s}^{-1}(T_{s,g})$, we can extract the time series that are approximately uncorrelated in each season of each year,

$$\boldsymbol{\eta}_s(t,\omega) = \hat{\mathbf{L}}_s^{-1}(T_{s,g}) \left(\mathbf{a}_s(t,\omega) - \hat{\boldsymbol{\mu}}_s \right).$$
(16)

Figure 11. Statistics of Jun-Aug daily maximum temperature of MPI-ESM1-2-LR dataset and the emulations. All the statistics are evaluated in 2090-2099 of the SSP5-8.5 scenario. (a) Mean anomaly from 1850-1900; (b) Standard deviation; (c) Anomaly of 97.5% quantile of local TMX distribution from the 1850-1900 value.

The autocorrelation of each component of η_s will be used to generate Gaussian processes. The remaining procedures for constructing the emulator are the same as in §3.2 and therefore not repeated here for conciseness.

Although the generalization introduced in (13-15) has the potential to improve the 453 performance of the emulator, it is only applicable when the data are sufficient to obtain 454 converged time-dependent covariance matrices. A minimum requirement for the amount 455 of data is that the number of samples for computing the covariance matrix (14) must 456 exceed the number of EOFs, or equivalently the size of $\Sigma_s(t)$. This requirement is not 457 satisfied by the CNRM-CM6-1-HR dataset. For example, in Northern Hemisphere sum-458 mer of every year we have 92 samples to compute $\Sigma_s(t)$, but the number of EOFs used 459 in the emulator is 2,000. As a result, the computed covariance matrix is not even full 460 rank, consisting of spurious correlations that contaminate the dependence on time or global 461 mean temperature. 462

To distinguish from the emulator introduced in §3.2, all the results generated using (13-15) will be termed as COV emulations. Both types of emulators are applied to the MPI-ESM1-2-LR dataset to compare their performance. Different from the CNRM-CM6-1-HR dataset that requires 2,000 EOFs to represent 95% of the total variance, only 1,000 EOFs are sufficient to model the MPI-ESM1-2-LR dataset due to lower spatial resolutions. All the 50 realizations of the historical and SSP5-8.5 scenarios are used to compute the EOFs and train the stochastic emulators of the EOF time series.

470 Since the error of emulated statistics were highest in SSP585 2090-2099 for the CNRM471 CM6-1-HR dataset, we focus on this time window to compare the performance of the
472 emulators. The results are visualized in figure 11. Overall the warming trend predicted
473 by MPI-ESM1-2-LR model is less pronounced than the CNRM-CM6-1-HR model, which

Figure 12. (a) Absolute and (b) Relative root-mean-square error of emulated statistics versus the number of realizations used for training the emulator. The statistics are evaluated in SSP5-8.5 2090-2099 Jun-Aug. Dashed lines: error of 50 emulations; Solid lines: error of 50 COV emulations. Blue, green, black: error of the mean, standard deviation, and 97.5% quantile. The relative errors in (b) are normalized by the values associated with the smallest N_{ω} .

is consistent with previous studies on equilibrium climate sensitivity of ESMs (Tokarska 474 et al., 2020). In figure 11a, the error of the mean anomaly of both emulators are almost 475 identical, which is expected since the same linear model is adopted for the seasonal mean 476 of EOF coefficients. The error of local standard deviation, as shown in panel b, is sig-477 nificantly reduced by modeling the variations of covariance matrix. For example, the high-478 est errors in North Africa and the Southern Ocean are decreased by approximately $2^{\circ}C$, 479 which confirms the speculation in §4.1 that these errors are mostly associated with time-480 dependent cross-mode correlations. As a result of more accurate estimation of local vari-481 ance in COV emulations, the quantiles in panel c are also reproduced with lower errors. 482

To assess the influence of ensemble size of the training data on both emulators, we 483 calculated the root-mean-square error (RMSE) of the emulated statistics. The results 484 are reported in figure 12 for the mean, standard deviation, and 97.5% quantile in SSP5-485 8.5 2090-2099 Jun-Aug. When N_{ω} realizations are available for training the emulator, 486 the true statistics \mathcal{Q} are also evaluated using the same N_{ω} realizations, while the em-487 ulators are always performed 50 times to generate converged statistics, \mathcal{Q} . In panel a, 488 compared with the constant-covariance emulator (dashed lines), the COV emulator (solid 489 lines) achieves approximately 40% error reduction in the standard deviation and 30%490 in the quantile. However, the COV emulator requires at least ten realizations to ensure 491 the positive definiteness of the covariance matrices. To highlight the dependence of em-492 ulation error on the ensemble size N_{ω} , the RMSE is normalized by the value associated 493 with the smallest N_{ω} attempted. The results are shown in figure 12b. For the constant-494 covariance emulator (dashed lines), as the size of ensemble is increased from one to ten, 495 the RMSE of mean, standard deviation and quantile are respectively decreased by 12%, 496 4.5% and 3.0%. These error reductions suggest that the emulation accuracy is generally 497 improved when the impact of climate internal variability is alleviated in the training data. 498 Such a trend is also consistent with conclusions of previous studies (Tebaldi et al., 2021) 499 that approximately ten realizations are required to capture the ensemble variance ac-500 curately. As the ensemble size reaches 50, further error reduction becomes negligible for 501 the standard deviation (green dashed) and quantile (black dashed), suggesting dimin-502 ishing returns from larger training datasets. In contrast, the COV emulator shows con-503 tinued improvement, with a reduction in error of 1.4% for the standard deviation and 504 4.0% for the quantile, since larger-ensemble data can still help improve the emulated co-505 variance matrices. Despite these gains, the COV emulator constructed with ten ensem-506 ble members already provides an accurate estimation of the statistics of extreme tem-507 perature. These results indicate that as long as the amount of training data are suffi-508

cient to construct the COV emulator, the performance of the emulator is robust against the ensemble size of realizations.

511 5 Conclusions and Discussion

We have developed a framework of a spatially resolved stochastic emulator that es-512 timates the full statistics of climate extremes. The emulator was trained and tested us-513 ing the daily maximum temperature data from CNRM-CM6-1-HR and MPI-ESM1-2-514 LR Earth system simulations in CMIP6. To reduce the dimensionality of the global cli-515 mate system and achieve speedy emulations, we extract empirical orthogonal functions 516 of daily maximum temperature data and assume their shapes remain unchanged across 517 different climate change scenarios. The time series of EOF coefficients are decomposed 518 as the combination of long term trends of seasonal statistics and conditionally Gaussian 519 daily fluctuations. The former, including seasonal mean and variance, are approximated 520 as linear or machine-learned functions of the global mean temperature, while the daily 521 fluctuations are modeled as Gaussian autoregressive processes that are scaled by the cross 522 correlations of different EOFs. While the statistics of the emulator, conditioned on sea-523 son and global mean temperature, are assumed to be Gaussian, the long term statistics 524 of the model do not produce normal distribution due to variation of the global mean tem-525 perature. However, the possibility of heavy tailed daily temperature fluctuations is not 526 covered and is left for future work. 527

The performance of the emulator is evaluated on the CNRM-CM6-1-HR dataset 528 due to its high spatial resolution. Trained on historical and SSP5-8.5 scenario, the em-529 ulated time series accurately reproduce the evolution of the seasonal mean and the Fourier 530 spectra of daily fluctuations. After generating the spatiotemporal evolution of the in-531 stantaneous daily maximum temperature, the emulator's performance is systematically 532 evaluated on the ten-year Jun-Aug statistics, including the mean, standard deviation, 533 quantile, and the full probability density function. Remarkably, the emulator reproduces 534 the quantile anomaly in response to climate change and effectively captures the non-Gaussian 535 profiles of the local PDF. When tested on the SSP1-2.6 scenario that is not included in 536 the training data, the full statistics are also accurately predicted, which demonstrates 537 the potential of the emulator to be applied to various climate change scenarios. While 538 using neural networks to represent the impact of global warming improves the emula-539 tor's performance on the training SSP5-8.5 scenario compared to linear functions, this 540 improvement does not extend to the SSP1-2.6 scenario used for validation. 541

Based on MPI-ESM1-2-LR large-ensemble datasets, we further developed the em-542 ulator by modelling the variation of the cross-mode covariance as linear functions of the 543 global mean temperature. Such a refinement helps reduce the root-mean-square error 544 of emulated local statistics by 50%. By progressively increasing the number of ensem-545 ble members in the training data, we assessed the impact of climate internal variabil-546 ity on performance of both emulators. Overall the RMSE of statistics decrease with larger 547 ensemble. When more than ten members are included, the accuracy of the constant-covariance 548 emulator approximately saturates, but COV emulator shows continued improvement. As 549 long as there are sufficient training data to construct the COV emulator, its performance 550 remains relatively stable regardless of the ensemble size of realizations. 551

There are numerous pathways for generalizing the emulator to further improve its 552 accuracy, and we outline a few possibilities below. First, the time-lagged covariance be-553 tween different EOFs can be included into the emulator to achieve a better estimation 554 of the full probability distribution of local temperature (Wan et al., 2021). Second, in-555 stead of using the global mean temperature as the driver, the emulator can be param-556 eterized using the emission history of greenhouse gases, the equivalent radiative forcing, 557 or aerosol concentrations (Castruccio et al., 2014; Freese et al., 2024). Such an exten-558 sion will take into account the memory effect and facilitate the application of the em-559

ulator into scenarios where the evolution of global mean temperature is non-monotonic. 560 Third, the Empirical Orthogonal Functions can be replaced by more state-of-the-art deep 561 learning methods, such as Autoencoders, to nonlinearly reduce the dimensionality of the 562 climate system (Kramer, 1991). Lastly, a recently proposed non-intrusive machine-learning framework shows promise for further improving the emulator's accuracy (Barthel Sorensen 564 et al., 2024). This approach focuses on learning a debiasing operator that takes the em-565 ulated time series of temperature fields as input and corrects them to better match the 566 reference data from ESMs. Once trained on a few scenarios, this debiasing operator can 567 be applied to correct the emulations in other unseen climate change scenarios. Despite 568 these potential enhancements, the emulator successful estimation of extreme tempera-569 ture statistics is promising and suggests its applicability to other variables, such as hu-570 midity, precipitation, and wind speed, which will better assist with risk management of 571 climate extremes. 572

Appendix A Temporal evolution of emulated quantile in SSP5-8.5 scenario

In this appendix, we provide more details about the temporal evolution of statis-575 tics of extreme temperature in SSP5-8.5 scenario. Similar to figure 8, we evaluate the 576 97.5% quantile of the local TMX using ten-year Jun-Aug data. The anomaly of quan-577 tiles against 1850-1900 reference are visualized in figure A1 and A2 from 2010 to 2089. 578 Overall the regions with the most rapid increase of extreme temperature are correctly 579 identified by the emulator. Two categories of error patterns can be observed. The first 580 type is relatively independent of time, such as the overestimated quantile in Greenland. 581 The second type is more stochastic, sometime even changing signs across different time 582 windows, such as the North America and southern Africa. These error patterns are prob-583 ably associated with the internal variability of the global climate system and require more 584 realizations of the Earth system simulations to converge. 585

⁵⁸⁶ Appendix B Emulated statistics in other seasons

This appendix presents the statistics of TMX across different seasons and their cor-587 responding emulation errors. The local standard deviation in 2090-2099 of the SSP5-8.5 588 scenario is shown in figure B1. In Dec-Feb, the error reaches its maximum in the Arc-589 tic, contrasting with the Jun-Aug pattern where the error peaks in the Southern Ocean 590 (c.f. figure B1). This seasonal difference is likely associated with the sea ice coverage. 591 During Dec-Feb, Antarctic sea ice consistently retreats almost to the coastline in both 592 historical and global warming scenarios. Therefore, the standard deviation of TMX in this season is less affected by warming conditions compared to Jun-Aug. Mar-May and 594 Sep-Nov present a more complex picture. During these transitional seasons, sea ice cov-595 erage in both polar regions is highly sensitive to climate change. The emulator strug-596 gles to capture the associated trends in standard deviations, resulting in high errors in 597 these areas. The error patterns of 97.5% quantile are analogous to the standard devi-598 ation, as shown in figure B2. 599

600 Open Research

All code to reproduce this work is available at https://github.com/mzwang2012/ sEM_TMX.git. The raw data from CMIP6 were retrieved through the Earth System Grid Federation interface https://aims2.llnl.gov/search/cmip6/.

This research was part of the Bringing Computation to the Climate Challenge (BC3)

project and supported by Schmidt Sciences through the MIT Climate Grand Challenges.

Figure A1. Extreme anomaly of ten-year Jun-Aug daily maximum temperature, quantified by the 97.5% quantile of local TMX distribution. The quantiles are evaluated for SSP5-8.5 scenario within 2010-2019, 2020-2029, 2030-2039, 2040-2049, respectively. Reference: 1850-1900 Jun-Aug 97.5% quantile of TMX.

Figure A2. Same as figure A1, but shown for 2050-2059, 2060-2069, 2070-2079, 2080-2089, respectively.

Figure B1. Standard deviation of ten-year seasonal daily maximum temperature, evaluated for Dec-Feb, Mar-May, and Sep-Nov in 2090-2099 of the SSP5-8.5 future scenario.

Figure B2. Extreme anomaly of ten-year seasonal daily maximum temperature, quantified by the 97.5% quantile of local TMX distribution. The quantiles are evaluated for Dec-Feb, Mar-May, and Sep-Nov in 2090-2099 of the SSP5-8.5 future scenario.. Reference: 1850-1900 97.5% quantile of TMX of each season.
